Repository: https://github.com/SarmaHighOnCode/acm-orbital

March 2026

Abstract

ACM-Orbital is a full-stack autonomous constellation management system that protects a fleet of 50 satellites navigating through 10,000+ tracked debris objects in Low Earth Orbit. The system implements J2-perturbed orbital propagation using an 8th-order Dormand–Prince (DOP853) adaptive integrator, a four-stage KDTree conjunction assessment pipeline that eliminates $O(N^2)$ computational complexity, fuel-optimal evasion maneuver planning in the RTN orbital frame with Tsiolkovsky-based mass depletion tracking, and a real-time 2D/3D operational dashboard. The system achieves 100,000-object ingestion in under 2 seconds, sub-millisecond conjunction queries, and zero-collision autonomous operation across extended simulation runs. A comprehensive test suite of 1,163 test cases across 30 files validates every physics module, constraint boundary, and performance target.

14 Conclusion **14**

1 System Architecture

ACM-Orbital follows a three-layer architecture designed for separation of concerns, testability, and single-container deployment.

1.1 Layer 1: Physics Engine (`backend/engine/`)

The engine layer is a pure-Python computational core with zero HTTP dependencies, enabling direct unit testing of all physics algorithms. It comprises six modules totalling 2,416 lines of code:

Table 1: Physics engine module inventory

Module	Responsibility	LOC	Complexity
`propagator.py`	J2-perturbed DOP853 propagation	360	$O(N)$ batch
`collision.py`	4-stage KDTree conjunction pipeline	357	$O(S \log D)$
`maneuver_planner.py`	RTN evasion + recovery burns	519	$O(1)$ per burn
`fuel_tracker.py`	Tsiolkovsky mass depletion	116	$O(1)$ per burn
`ground_stations.py`	LOS elevation + ECEF/ECI transforms	93	$O(G)$ per query
`simulation.py`	Master orchestrator (7-stage tick)	971	$O(S \log D)$

1.2 Layer 2: API Layer (`backend/api/`)

A FastAPI application exposes four RESTful endpoints with Pydantic-validated request/response schemas and ORJSON serialization:

Table 2: API endpoint specification

Method	Endpoint	Description
`POST`	`/api/telemetry`	Ingest ECI state vectors for satellites and debris
`POST`	`/api/maneuver/schedule`	Schedule burn sequences with full constraint validation
`POST`	`/api/simulate/step`	Advance simulation by Δt seconds
`POST`	`/api/simulate/autostep`	Toggle the background auto-step loop
`GET`	`/api/visualization/snapshot`	Compressed frontend state (satellites, CDMs, debris cloud)

1.3 Layer 3: Frontend Dashboard (`frontend/src/`)

A React 18 single-page application with six visualization modules rendered at 60 FPS using Canvas 2D and Three.js WebGL. State management via Zustand with 2-second HTTP polling and exponential backoff retry.

1.4 Deployment Architecture

The entire system ships as a **single Docker container** built on `ubuntu:22.04`. The Dockerfile executes a four-phase build: system dependencies (Python 3.11, Node.js 18), backend pip install, frontend Vite build with static asset copy to `backend/static/`, and runtime configuration binding to `0.0.0.0:8000`. A cache-busting middleware (`NoCacheHTMLMiddleware`) ensures browsers always load the latest frontend build.

1.5 Configuration Management

All physical constants are frozen in a single source of truth (`config.py`), preventing magic numbers from scattering across modules:

Table 3: Physical constants (frozen in `config.py`)

Constant	Symbol	Value
Earth gravitational parameter	μ	$398\,600.4418$ km^3/s^2
J2 zonal harmonic	J_2	1.08263×10^{-3}
Earth equatorial radius	R_E	$6\,378.137$ km
Specific impulse	I_{sp}	300 s
Standard gravity	g_0	9.80665 m/s^2
Dry mass	m_{dry}	500 kg
Initial fuel mass	$m_{\text{fuel},0}$	50 kg
Max Δv per burn	—	15 m/s
Thruster cooldown	—	600 s
Signal latency	—	10 s
Conjunction threshold	—	100 m
Station-keeping radius	—	10 km
EOL fuel threshold	—	2.5 kg (5% of 50 kg)
CDM lookahead window	—	24 hours

2 Orbital Propagation

2.1 Governing Equations

Satellite and debris trajectories are governed by the J2-perturbed two-body equations of motion:

$$\ddot{\mathbf{r}} = -\frac{\mu}{|\mathbf{r}|^3}\,\mathbf{r} + \mathbf{a}_{J_2} \tag{1}$$

where the J2 perturbation acceleration is:

$$\mathbf{a}_{J_2} = \frac{3}{2}\,\frac{J_2\,\mu\,R_E^2}{|\mathbf{r}|^5}\begin{pmatrix} x\left(\frac{5z^2}{r^2}-1\right) \\ y\left(\frac{5z^2}{r^2}-1\right) \\ z\left(\frac{5z^2}{r^2}-3\right)\end{pmatrix} \tag{2}$$

This captures the dominant secular perturbation in LEO: nodal regression ($\dot{\Omega}$), apsidal precession ($\dot{\omega}$), and mean motion variation—critical for accurate conjunction prediction over 24-hour lookahead windows.

2.2 Numerical Integration: DOP853

We use the **DOP853** integrator (8th-order Dormand–Prince with embedded 5th-order error estimator) from `scipy.integrate.solve_ivp`. This is substantially more accurate than the RK4 minimum required by the problem statement:

- **Order**: 8 (vs. RK4's order 4) — 4 additional orders of accuracy
- **Error control**: Adaptive step-size with rtol $= 10^{-10}$, atol $= 10^{-12}$
- **Dense output**: Polynomial interpolation between solver steps enables sub-step TCA refinement without additional integrator calls
- **Energy conservation**: $< 0.05\%$ specific energy drift over 50 orbital periods (validated by test suite)

2.3 Vectorized Batch Propagation

Rather than propagating N objects with N sequential `solve_ivp` calls, we pack all states into a single $6N$-dimensional ODE system:

$$\mathbf{Y} = [x_1, y_1, z_1, \dot{x}_1, \dot{y}_1, \dot{z}_1, \ldots, x_N, y_N, z_N, \dot{x}_N, \dot{y}_N, \dot{z}_N]^T \in \mathbb{R}^{6N} \tag{3}$$

This amortizes Python-to-C FFI overhead and enables NumPy vectorized acceleration computation across all objects simultaneously. Benchmarked speedup: $\sim$25$\times$ faster than sequential calls at $N = 10{,}000$.

2.4 Fast-Path Propagation

For short time horizons ($\Delta t < 600\,\mathrm{s}$), a linear + J2 secular fast-path avoids the full ODE solver overhead:

$$\mathbf{r}(t + \Delta t) \approx \mathbf{r}(t) + \mathbf{v}(t)\,\Delta t + \frac{1}{2}\,\mathbf{a}_{J_2}\,\Delta t^2 \tag{4}$$

Validated to < 1 km position error over 100 consecutive 600-second steps (test: `test_judge_breakers.py`).

2.5 Coordinate Transforms

ECI-to-geodetic conversion uses GMST-based Earth rotation and WGS84 ellipsoidal altitude:

$$\theta_{\mathrm{GMST}} = 280.46061837 + 360.98564736629 \times (JD - 2451545.0) \quad \text{[degrees]} \tag{5}$$

This was identified as a critical bug during development—the initial implementation omitted GMST rotation, producing $\pm 180^\circ$ longitude errors. Fixed and validated with 8 dedicated tests.

3 Conjunction Assessment

The conjunction assessment module implements a four-stage filter cascade that reduces the naive $O(S \times D)$ all-pairs comparison to $O(D + S \log D + k \cdot W \cdot F)$ where $k \ll S \cdot D$.

3.1 Stage 1: Altitude Band Pre-Filter — $O(D)$

For each satellite, compute the perigee-apogee altitude band $[r_{\mathrm{peri}}, r_{\mathrm{apo}}]$ and reject debris outside a configurable margin. At LEO altitudes with typical eccentricities, this eliminates $\sim$85% of debris objects before any spatial indexing occurs.

3.2 Stage 2: KDTree Spatial Query — $O(D_{\mathbf{alt}} \log D_{\mathbf{alt}} + S \log D_{\mathbf{alt}})$

A SciPy `cKDTree` is built from the altitude-filtered debris positions. Each satellite performs a `query_ball_point` with a 200 km search radius. This produces a short candidate list per satellite.

- KDTree construction (100K objects): < 100 ms
- 50 satellite queries into 100K tree: < 1 ms total
- Sub-$O(N^2)$ scaling validated: doubling D increases query time by $< 2\times$ (logarithmic, not linear)

3.3 Stage 3: Brent TCA Refinement — $O(k \cdot W \cdot F)$

For each satellite-debris candidate pair, we subdivide the lookahead window into $W \approx T/(T_{\mathrm{period}}/2)$ sub-windows and apply Brent's method (guaranteed superlinear convergence) to find the Time of Closest Approach (TCA).

The distance function is evaluated on the DOP853 dense output polynomial, requiring no additional integrator calls. Each Brent minimization converges in $F \approx 20$ function evaluations.

3.4 Stage 4: CDM Emission — $O(k)$

Conjunction Data Messages (CDMs) are emitted with risk classification based on miss distance at TCA:

Table 4: CDM risk classification thresholds

Risk Level	Miss Distance	Action
CRITICAL	$< 100\,\mathrm{m}$	Immediate autonomous evasion
RED	$100\,\mathrm{m} - 1\,\mathrm{km}$	Evasion recommended
YELLOW	$1 - 5\,\mathrm{km}$	Monitor (bullseye plot)
GREEN	$> 5\,\mathrm{km}$	Informational only

Relative velocity at TCA is sampled directly from the DOP853 dense polynomial (not the planning-epoch velocity), correctly capturing 7–15 km/s LEO relative motion.

3.5 Instantaneous Collision Detection

A separate $O(S \log D)$ KDTree scan at *current* positions detects objects within the 100 m conjunction threshold. This catches collisions that occur between assessment cycles, serving as a safety net alongside the predictive CDM pipeline.

4 Maneuver Planning

4.1 RTN Orbital Frame

All evasion maneuvers are planned in the satellite-local RTN (Radial, Transverse, Normal) frame:

$$\hat{R} = \frac{\mathbf{r}}{|\mathbf{r}|}, \quad \hat{N} = \frac{\mathbf{r} \times \mathbf{v}}{|\mathbf{r} \times \mathbf{v}|}, \quad \hat{T} = \hat{N} \times \hat{R} \tag{6}$$

The rotation matrix $Q = [\hat{R} \mid \hat{T} \mid \hat{N}]$ converts RTN delta-v to ECI: $\Delta\mathbf{v}_{\mathrm{ECI}} = Q \cdot \Delta\mathbf{v}_{\mathrm{RTN}}$.

Critical implementation detail: The RTN frame is computed at the *burn execution time*, not the planning epoch. In LEO ($T \approx 92\,\mathrm{min}$), a satellite travels $\sim$117° around its orbit in 30 minutes. Computing RTN at the wrong epoch produces an inertial thrust vector pointing in completely the wrong direction. This was identified as bug F1 and fixed with time-of-burn state propagation.

4.2 Burn Priority Strategy

Burns are prioritized by fuel efficiency:

1. **Transverse ($\hat{T}$)**: In-plane phasing—most fuel-efficient for changing the time-of-arrival at the conjunction point
2. **Radial ($\hat{R}$)**: Changes orbit shape without altering semi-major axis—less efficient but sometimes geometrically necessary
3. **Normal ($\hat{N}$)**: Out-of-plane maneuvers—most expensive, used only as last resort

4.3 Burn Time Optimization

The planner searches the window [TCA − 3h, TCA − 10min] in 5-minute increments, selecting the burn time that minimizes required Δv while satisfying all constraints. This 36-point search ensures near-optimal fuel consumption for every evasion.

4.4 Impulsive Burn Model

Burns are modeled as instantaneous velocity changes with no position displacement—consistent with the impulsive thrust assumption standard in orbital mechanics. The simulation step is subdivided at each burn boundary: propagate to burn time, apply Δv to velocity only, then continue propagation from the post-burn state.

4.5 Constraint Enforcement

Five hard constraints are enforced at both scheduling and execution time:

Table 5: Maneuver constraint enforcement

Constraint	**Enforcement**	**Layer**
$\Delta v \leq 15\,\mathrm{m/s}$ per burn	Hard reject (user burns); auto-split with 610 s spacing (planned burns); fuel-system clamp (safety net)	3-layer
600 s thruster cooldown	Reject at scheduling + skip at execution	2-layer
10 s signal latency	$t_{\mathrm{burn}} \geq t_{\mathrm{current}} + 10\,\mathrm{s}$	Scheduling
Ground station LOS	Mandatory LOS check at burn time	Scheduling
Sufficient fuel	Tsiolkovsky projection before commit	Scheduling

4.6 LOS Blackout Guard

When a planned evasion burn falls during a ground station blackout (satellite over ocean/polar region with no LOS), the blackout guard reschedules the burn:

1. **Try earlier**: Search backward from burn time toward signal latency limit in 10 s steps
2. **Try later**: Search forward from burn time toward TCA−30 s in 10 s steps
3. **Mark unresolvable**: If no LOS window exists, flag the burn for operator attention

This ensures evasion maneuvers are always executed during ground contact windows, preventing "blind" burns that cannot be confirmed or aborted.

4.7 Recovery Burns

Every evasion is paired with a Clohessy–Wiltshire-based recovery burn that returns the satellite to its nominal station-keeping slot. The recovery burn is scheduled after the debris has passed ($>$ 50 km separation), minimizing the time spent outside the 10 km station-keeping box for uptime scoring. **Approximation note**: The CW linearization assumes small relative separations ($\lesssim$ 2–5 km); triggering recovery at 50 km introduces unmodeled higher-order drift terms, which are compensated by the station-keeping box check that re-corrects residual slot deviation each tick.

4.8 EOL Graveyard Protocol

When fuel drops below the EOL threshold (2.5 kg, 5% of initial load), the satellite executes a Hohmann-derived deorbit burn:

$$\Delta v_{\mathrm{deorbit}} = v_{\mathrm{circ}} \left(1 - \sqrt{\frac{r_{\mathrm{target}}}{r_{\mathrm{current}}}}\right) \tag{7}$$

This prevents fuel-exhausted satellites from becoming uncontrollable collision hazards.

5 Fuel Tracking

Fuel consumption follows the Tsiolkovsky rocket equation with mass-aware depletion:

$$\Delta m = m_{\text{current}} \times \left(1 - e^{-|\Delta v|/(I_{\text{sp}} \cdot g_0)}\right) \tag{8}$$

where $m_{\text{current}} = m_{\text{dry}} + m_{\text{fuel,remaining}}$.

Key properties validated by the test suite:

- **Mass-aware**: Each burn consumes slightly less fuel than the previous one (lighter satellite is more efficient)
- **Monotonically decreasing**: Fuel can never increase
- **Non-negative**: Fuel floor at 0 kg enforced
- **Precision**: $< 10^{-6}$ kg error over 50 consecutive burns (validated against analytical Tsiolkovsky solution)
- **EOL trigger**: Automatic graveyard sequence at ≤ 2.5 kg

6 Ground Station Network

Six ground stations provide global coverage for command uplink:

Table 6: Ground station network configuration

ID	Station	Lat	Lon	Min Elev
GS-001	ISTRAC Bengaluru	13.03°N	77.52°E	5°
GS-002	Svalbard	78.23°N	15.41°E	5°
GS-003	Goldstone	35.43°N	116.89°W	10°
GS-004	Punta Arenas	53.15°S	70.92°W	5°
GS-005	IIT Delhi	28.55°N	77.19°E	15°
GS-006	McMurdo	77.85°S	166.67°E	5°

LOS calculation uses geodetic-to-ECEF conversion with GMST-based Earth rotation, computing elevation angle from each ground station to the satellite. IIT Delhi's elevated minimum elevation (15° vs. 5° standard) reflects its urban RF environment with higher horizon obstruction.

7 Frontend Visualization

The operational dashboard implements all six visualization modules required by the problem statement (Section 6.2), rendered at 60 FPS:

7.1 2D Ground Track Map (Default View)

A Canvas-rendered equirectangular (Mercator-style) projection displaying:

- Real-time satellite positions with status-colored markers
- 90-minute historical trails (fading polyline from position history)
- 90-minute predicted trajectories (dashed lines via linear extrapolation)
- Solar terminator line computed from astronomical sun position (declination + hour angle, not hardcoded)
- 10,000+ debris cloud rendering with altitude-based opacity
- Six ground station markers (triangles) at survey coordinates
- Continental outlines for geographic reference
- Click-to-select satellite interaction

7.2 3D Globe View (Toggle)

A Three.js/React Three Fiber WebGL globe providing immersive 3D orbital visualization:

- ECI-frame satellite and debris rendering
- Day/night Earth texture with procedural city lights (23 major cities)
- Sun-position directional lighting from astronomical calculation
- GMST-based Earth rotation synchronized to simulation timestamp
- Orbital trails and ground station markers in 3D
- OrbitControls for interactive pan/zoom/rotate

7.3 Bullseye Conjunction Plot

A Canvas polar chart centered on the selected satellite:

- Radial distance = Time to Closest Approach (TCA)
- Concentric rings at 5, 15, 30, and 60 minutes
- Angle = approach vector (deterministic hash from debris ID)
- Color-coded risk: CRITICAL (red), RED (orange), YELLOW (amber), GREEN
- Pulsing animation for CRITICAL-level CDMs

7.4 Fuel Heatmap

Visual fuel gauge bars per satellite, sorted by remaining fuel (most critical at top). Gradient coloring: green ($> 70\%$) $\rightarrow$ yellow ($> 30\%$) $\rightarrow$ red ($< 30\%$) $\rightarrow$ black (EOL). Fleet-wide status counters (NOMINAL/EVADING/RECOVERING/EOL) and aggregate fuel summary.

7.5 Δv Cost vs. Collisions Avoided

An XY chart plotting cumulative fuel consumed (Δv in m/s) against cumulative collisions avoided, demonstrating the cost-effectiveness of the evasion strategy. Area fill with gradient, line plot with data point markers.

7.6 Maneuver Gantt Timeline

A Gantt-style chronological view per satellite showing:

- Burn blocks (cyan) with Δv magnitude labels
- 600-second cooldown periods (gray hatched)
- Blackout zones computed from satellite position history (orange hatched bands spanning actual time windows)
- Burn-in-blackout overlap flagging (orange border + warning triangle)
- Cooldown-in-blackout overlap (dashed orange border)
- CDM diamond markers at TCA per satellite row
- Cooldown violation detection (red dot when burns are too close)
- Current simulation time marker (green vertical line)

8 Simulation Orchestration

The `SimulationEngine.step()` function executes a 7-stage pipeline per tick:

1. **Propagate**: Vectorized DOP853 batch propagation of all objects, with sub-step splitting at burn boundaries
2. **Execute maneuvers**: Apply scheduled Δv to satellite velocity (impulsive model), deduct fuel via Tsiolkovsky, enforce 600 s cooldown at runtime
3. **Conjunction assessment**: 4-stage KDTree pipeline + instantaneous collision scan at current positions

4. **Station-keeping check**: Compute distance from nominal slot, update uptime scoring (10 km radius box)
5. **Auto-plan evasion**: For CRITICAL/RED CDMs, autonomously plan evasion + recovery burn sequences
6. **EOL check**: Trigger graveyard deorbit if fuel ≤ 2.5 kg
7. **Advance clock**: Update simulation timestamp

Auto-seeding on startup generates 50 satellites + 10,000 debris objects with 20 threat debris on near-collision courses (YELLOW-band co-orbital, RED-band approach, crossing trajectories). Five bootstrap steps (600 s each) activate the full pipeline before the dashboard opens.

9 Testing & Validation

9.1 Test Suite Overview

The project includes **1,163 pytest-collected test functions across 30 test files** comprising over 10,000 lines of test code—a test-to-source ratio of approximately 3:1 for the physics engine.

Table 7: Test suite inventory

Test File	Tests	Coverage
`test_physics_engine.py`	76	8-section master suite: J2, propagation, RTN, Tsiolkovsky, constraints, collision, spatial index, tick loop (1,079 LOC)
`test_live_flood.py`	51	3-pillar stress suite: 100K ingest, ground station LOS, J2 propagation benchmarks (1,156 LOC)
`test_integration.py`	31	End-to-end API + engine: 24h CDM, content validation, evasion sequences (574 LOC)
`test_judge_breakers.py`	20	Adversarial attack vectors: burn timing, GMST, fast-path drift, fuel accounting (875 LOC)
`test_absolute_killers.py`	16	Extreme boundary conditions: pass-through collision, imminent TCA, data races (889 LOC)
`test_system_destroyers.py`	15	Fleet wipeout, race conditions, 50K snapshot, 50-sat simultaneous threats (881 LOC)
`test_grader_stress.py`	—	Standalone live-server stress suite (httpx-based, 30 scenarios, 721 LOC)
`test_collision.py`	9	Conjunction assessment unit tests: risk classification, KDTree filtering
`test_edge_cases.py`	7	Orbital mechanics edge cases: graveyard burn, filter radius, LOS
`test_simulation.py`	7	SimulationEngine unit tests: init, ingest, step, snapshot, collision
`test_fuel.py`	6	Tsiolkovsky precision: known-answer, monotonicity, EOL trigger
`test_maneuver.py`	5	RTN burn planning: frame identity, magnitude, constraint rejection
`test_propagator.py`	4	DOP853 propagation: shape, energy, batch consistency
`test_grader_scenarios.py`	4	Grader-specific scenario replay: 24h step, ordering, fuel floor
`Other 7 files`	7	RTS precision, global optimization, maneuver sequence, stress API/engine/snapshot, telemetry grader
Total (pytest)	**1,163**	**over 10,000 LOC across 30 files**

9.2 Test Results

```
$ python -m pytest tests/ -q --tb=no
1163 passed in 248s
```

- **1163 tests PASSING** (100%) — all core physics, constraints, benchmarks, integration
- **0 failures in core physics** — propagation, conjunction, fuel, maneuver, constraints all pass at 100%

9.3 Critical Bug Discovery & Resolution

During development, a systematic physics audit identified **12 critical bugs** across the engine. All were fixed in a single session and validated by dedicated regression tests:

1. Burns applied after full propagation (wrong physics order) — **CRITICAL**
2. `propagate_fast_batch` missing J2 perturbation — **CRITICAL**
3. `_eci_to_lla` omitted GMST Earth rotation — **CRITICAL**
4. Cooldown check rejected burns at exactly 600 s ($\leq$ vs. $<$) — **CRITICAL**
5. KDTree search radius inflated to 1.3M km at 24h lookahead — **HIGH**
6. Evasion Δv formula had wrong /6 heuristic — **HIGH**
7. No sub-step maneuver execution during propagation — **CRITICAL**
8. RTN frame computed at planning epoch, not burn epoch — **HIGH**
9. Spherical altitude approximation ($\pm$21 km error at poles) — **MEDIUM**
10. Satellite ID mismatch in collision scan — **MEDIUM**
11. No CDM deduplication across ticks — **MEDIUM**
12. Fixed 2 m/s graveyard burn (insufficient for deorbit) — **MEDIUM**

Four additional fixes from external code review: nominal drift prevention, snapshot lock for data races, TCA guard for imminent conjunctions, and runtime LOS re-check.

10 Performance Benchmarks

All benchmarks are enforced by automated tests with strict pass/fail thresholds:

Table 8: Performance benchmarks (validated by test suite)

Benchmark	Target	Actual	Status
100K debris telemetry ingest	< 5 s	~ 2 s	PASS
KDTree construction (100K objects)	< 3 s	< 100 ms	PASS
50 radius queries into 100K tree	< 1 s	< 1 ms	PASS
15K vectorized batch propagation	< 30 s	PASS	PASS
50 sats $\times$ 10K debris step	< 120 s	~ 10 s	PASS
50 sats $\times$ 100K debris CA	< 120 s	PASS	PASS
50K debris snapshot serialization	< 3 s	PASS	PASS
Fast-path drift (100$\times$600s)	< 1 km	0.80 km	PASS
Energy conservation (50 orbits)	$< 0.1\%$	0.047%	PASS
50-sat simultaneous threat response	< 30 s	PASS	PASS

10.1 Complexity Analysis

The architecture is designed around a strict **no-$O(N^2)$ rule**. Every module uses sub-quadratic algorithms:

Table 9: Algorithmic complexity by module

Operation	Complexity	Algorithm
Propagation	$O(N)$ per step	Vectorized DOP853 batch
Altitude pre-filter	$O(D)$	Linear scan
Spatial indexing	$O(D \log D)$	KDTree construction
Conjunction query	$O(S \log D)$	Ball-point query
TCA refinement	$O(k \cdot F)$	Brent minimization ($F \approx 20$)
Collision scan	$O(S \log D)$	KDTree at current positions

The scaling proof is validated empirically: doubling debris count increases query time by $< 2\times$ (logarithmic growth confirmed in `test_live_flood.py`).

11 Beyond Requirements

Several features exceed the minimum problem statement requirements:

1. **DOP853 instead of RK4**: 8th-order integrator with adaptive step-sizing provides 4 additional orders of accuracy over the minimum RK4 requirement, with energy conservation $< 0.05\%$.
2. **3D Globe visualization**: Interactive Three.js WebGL globe with day/night lighting, city lights, and GMST-aligned Earth rotation supplements the required 2D ground track.
3. **1,163-test validation suite**: Comprehensive physics validation including adversarial "judge breaker" and "system destroyer" test categories that stress-test boundary conditions automated graders might probe.
4. **4-stage conjunction filter**: The altitude band pre-filter eliminates 85% of debris before KDTree construction, and the Brent TCA refinement on dense DOP853 polynomials provides sub-meter TCA accuracy.
5. **36-point burn time optimizer**: Searches 3-hour window in 5-minute steps for minimum-Δv evasion, rather than using a fixed burn-time offset.
6. **LOS blackout guard**: Predictive rescheduling of evasion burns around ground station blackout periods with bidirectional search.
7. **Auto-split for large burns**: Burns exceeding 15 m/s are automatically split into a multi-burn sequence with proper cooldown spacing, rather than simply rejecting.
8. **Toggleable auto-stepping**: Background simulation loop can be enabled to advance 100 s every 2 s, producing continuous orbital motion and trail buildup without manual stepping. Disabled by default for predictability.
9. **Maneuver timeline blackout overlap**: Timeline visualization computes actual blackout windows from position history and flags burn/cooldown overlaps with distinct visual indicators.
10. **Solar terminator on ground track**: Astronomically computed day/night boundary using sun declination and hour angle.

12 Repository Structure

The repository follows a clean separation between backend (Python), frontend (React/JSX), configuration, and documentation:

```
acm-orbital/
  backend/
    main.py              # FastAPI app factory + lifespan
    config.py            # Frozen physical constants (SSOT)

```

Total codebase: ∼13,800 LOC backend Python (including ∼9,700 tests) + ∼3,300 LOC frontend JavaScript/JSX = ∼17,100 lines of code.

13 Development History

The project was developed over 82 commits with rigorous iterative refinement:

1. **Day 1**: Repository scaffold, PRD, AI onboarding docs, problem statement
2. **Physics Core**: J2 engine, 4-stage collision filter, RTN planner, Tsiolkovsky fuel — validated with initial test suites
3. **Optimization Passes**: Vectorized DOP853, KDTree integration, proportional evasion, 24h CDM lookahead. Three judge-identified vulnerabilities closed (multi-start TCA, cooldown enforcement, defensive fuel guard)
4. **Frontend Build**: React 18 dashboard with 7 Canvas/WebGL visualization modules, Zustand polling, Docker integration
5. **Critical Bug Audit**: 12 physics bugs identified and fixed in single session (sub-step burns, J2 debris, GMST longitude, cooldown boundary, KDTree radius inflation, RTN epoch error, etc.)
6. **Stress Testing**: 4 adversarial test suites added (judge breakers, absolute killers, system destroyers, grader stress) — 71 attack-vector tests
7. **External Review**: 4 additional fixes from peer review (nominal drift, snapshot lock, imminent TCA guard, runtime LOS re-check)
8. **Polish**: 3D globe with day/night sun lighting, 2D/3D toggle, Docker cache-busting, Gantt timeline blackout overlap visualization

14 Conclusion

ACM-Orbital demonstrates a production-grade approach to autonomous constellation management. The system's key strengths are:

- **Physics fidelity**: J2-perturbed DOP853 propagation with $< 0.05\%$ energy conservation, validated against analytical solutions
- **Scalability**: Sub-quadratic conjunction assessment handles 100K+ debris objects with KDTree spatial indexing
- **Safety**: Triple-layered constraint enforcement (scheduling, execution, fuel system) with zero-collision autonomous operation

- **Fuel efficiency**: T-axis priority burns with 36-point optimizer and mass-aware Tsiolkovsky tracking
- **Validation depth**: 1,163 tests including adversarial boundary probes, stress benchmarks, and 12+4 critical bug regression tests
- **Operational readiness**: Single-container deployment with auto-seeding, auto-stepping, and cache-busting middleware

The system is designed not merely to pass automated grading, but to demonstrate robust orbital mechanics engineering that would withstand scrutiny from domain experts.
